Identifying cell and gene candidates in severe COVID-19 patients

Background: COVID-19 is an infectious disease driven by the virus SARS-CoV-2, which primarily infects lung epithelial cells. However, elderly patients usually develop severe lung inflammation and lung dysfunction, ultimately leading to respiratory failure (<u>Guan et al 2020</u>). The onset of the disease is characterised by a cytokine storm comprising several inflammatory mediators (<u>Pedersen et al 2020</u>), specially in severe cases of the disease. Many cell types orchestrate the immune response to the virus, but their relative contribution at the single-cell resolution is still unclear. Herein, our main goal is to identify which cell types and gene pathways are altered in the blood of patients with severe COVID-19.

Main research question: Which cell types and genes are altered when comparing blood immune cells from healthy versus COVID-19 patients.

Importance: Identifying such genes will allow us to: 1) better understand why severe COVID-19 patients develop stronger immune responses; 2) find potential cells for blockage or immune enhancement therapy or; 3) identify pathways that could be targeted pharmacologically.

Most of our cells are of good quality taking into account the number of genes, transcripts, mitochondrial genes and ribosomal genes detected from the cells,

Plot of most highly expressed genes - house-keeping genes, mitochondrial, ribosomal

As expected most genes detected are protein coding genes - the rest are filtered out

% reads per cell

Most cells do not show variation in their cell cycle score

Normalisation is done to

reads / UMIs

Feature selection

- Done to identify features that vary between our samples
- To enable us work with genes informative enough to help us separate our cells
- Highly expressed genes will show higher variance, to normalise this variation, the log of their mean expression is taken

Scaling and linear centering

- Done to give equal weight to all genes irrespective of expression level
- This step can also be used to exclude the effect of certain variables
- We regressed out effects due to number of genes, transcripts, percentage of mitochondrial genes, S.Score

Data integration

Remove batch effect

Cell Clustering

scRNA-seq - graph construction and clustering

The k-Nearest Neighbor (kNN) graph is a graph in which two vertices p and q are connected by an edge, if the distance between p and q is among the k-th smallest distances from p to other objects from P. The **Shared Nearest Neighbor (SNN)** graph has weights that defines proximity, or similarity between two edges in terms of the number of neighbors (i.e., directly connected vertices) they have in common.

Take-home messages:

Research Question:

Which cell types and genes are altered when comparing blood immune cells from healthy versus COVID-19 patients

Importance

1) better understand why severe COVID-19 patients develop stronger immune responses (identified DE-genes)

2) find potential cells for blockage or immune enhancement therapy (NK T-cells, NK cells)

3) identify pathways that could be targeted pharmacologically
